Future Colliders

Progress is not a straight line.

An Wang

In the post-LHC era, particle physics is at somewhat of an impasse. The Standard Model (SM) has held up to most experiments and observation, and its predictive power is now exhausted. There are tantalising hints at a theory beyond the Standard Model – in the form of CP-violation and dark matter – but as of yet all new ways to probe the SM for its weaknesses, to see the greater theory behind it, have yielded very little.

There are many planned investigations to attempt to identify physics Beyond the Standard Model that use the Large Hadron Collider (LHC), or plan to leverage the upgrades for the High Luminosity Large Hadron Collider (HL-LHC). However, now that the Higgs boson has been identified successfully, one of the most fruitful avenues for further research is the construction and operation of a lepton collider at the energy frontier, with sufficient centre-of-mass energy to produce Higgs bosons in large numbers.

This is what motivates the several proposals for future lepton colliders around the world today, that would operate to complement and expand the reach of particle physicists beyond what the LHC is currently capable of. These proposed lepton colliders are broadly split into two groups: linear colliders and circular colliders.

Linear colliders use two accelerator arms pointed towards a single interaction point, and in general are capable of high centre-of-mass energies. The main candidates for this style of collider are the International Linear Collider (ILC) and the Compact Linear Collider (CLIC).

Circular colliders use a similar layout to the LHC, with a circular accelerator capable of creating collisions at multiple different interaction points around the circumference of the ring, which permits multiple detectors. The downsides of a circular collider are that

lighter particles like electrons are more prone to energy losses via synchrotron radiation, limiting the centre-of-mass energies that a circular lepton collider can operate at. However, in exchange they tend to have much higher luminosities, allowing greater numbers of collisions and higher yields of certain processes or channels. The main candidates for circular colliders are the Future Circular Collider (FCC) and the Circular Electron Positron Collider (CEPC).

These proposed colliders share many of the same motivations, design considerations, features, and challenges, as does the ongoing international effort in research and development to make these colliders a reality.

2.1 The physics case for a lepton collider

With the observation of a Higgs boson with a mass of 125 GeV, based on data from the Large Hadron Collider, the Standard Model of particle physics is now functionally complete – all of its major predictions have been observed. This is a testament to its quality as a theory, where its predictive power and accuracy is one of the best in all of the sciences.

But despite this, a multitude of observations have shown that the Standard Model cannot be a complete theory of nature. Many phenomena have been observed that the Standard Model cannot predict, or that don't seem to interact with the Standard Model in any way.

Particle physicists are now forced to seek answers to three questions that the Standard Model cannot solve:

1. What is dark matter? Astrophysics observations support the existence of a neutral, weakly-interacting substance that composes around 85% of all mass in the universe. Yet this substance cannot be explained by any known form of matter, and is completely unprecedented by the Standard Model.
2. Why is there so little antimatter? The symmetries inherent in the Standard Model predict that the Big Bang would have created an equal quantity of matter and antimatter. Yet the universe today is dominated by matter.
3. Why does the Higgs field fill space and give mass to elementary particles? The existence of the Higgs field and the coupling of the Higgs boson to other particles can be understood from the Standard Model but their origin or cause is still unexplained.

In order to answer these questions, new theories of physics Beyond the Standard Model (BSM) have been made, and need to be experimentally tested. To do this, particle collider experiments at the energy frontier are needed. The Large Hadron Collider (LHC) has already been used extensively in searches for new physics, in the forms of new particles, rare and exotic decays, supersymmetry, and dark matter.

However, the running of a lepton collider at the energy frontier would be complementary to the LHC’s continuing physics programme – there are many events or channels that are inaccessible or difficult to examine in one environment that are much simpler or higher precision in the other. In this way, a lepton collider would help to improve and refine measurements already taken at the LHC, while also allowing physicists to examine new channels and decays that were not accessible to it. A number of processes and their discovery potential can be seen in Table 2.1.

This follows a historical pattern in particle physics – as the energy frontier advances, hadron colliders are used to discover new physics and new phenomena, followed by lepton colliders to examine these phenomena in higher precision.

2.1.1 Higgs physics

Of specific interest to searches at lepton colliders would be the Higgs boson itself. Many BSM models predict differences from the Standard Model in the Higgs sector – such as several Higgs bosons with different masses, composite Higgs, charged Higgs etc. The comparatively ‘quiet’ environment of a lepton collider allows higher precision measurements of the properties of the Higgs boson, placing better constraints on the presence of new physics. In addition, lepton colliders can easily operate at specific thresholds and “hot spots” for Higgs production, permitting a much greater number of events yielding Higgs bosons, and thus a greater sample to examine.

Additionally, the most common decay of the Higgs boson, at a branching ratio of 57.7%, is the $H \rightarrow b\bar{b}$ process. Despite the high branching ratio, the huge QCD backgrounds in a hadron collider have made this decay incredibly difficult to observe at the LHC – in fact, the $H \rightarrow b\bar{b}$ decay has only fairly recently been experimentally confirmed by the ATLAS experiment. However, in a lepton collider these QCD backgrounds are significantly smaller, meaning this decay channel is much easier to analyse, opening up a huge number of Higgs events for analysis and examination.

Another highly interesting process uniquely accessible to lepton colliders is the higgsstrahlung reaction: $e^+e^- \rightarrow Zh$. The decay of the Z boson into lepton pairs e^+e^- or

$\mu^+\mu^-$ allows high precision kinematic measurements of the process without directly measuring the Higgs boson itself. This allows unprecedented measurement of the Higgs mass, while also making measurements of missing energy possible. If the Higgs boson has invisible decays – such as dark matter particles or other undiscovered particles that don’t couple to the SM – the higgstrahlung process allows their existence to be identified.

[...] [High precision and model-independent measurement of the total rate of Higgs decay Γ_h]

[...] [Top-Higgs Yukawa coupling, which is highly sensitive to new physics, since it’s the strongest Higgs coupling. Minimum possible energy is 471 GeV, so only possible in the 500 GeV stage or later, depending on cross section.]

2.1.2 Top physics

In addition to the Higgs, the top quark is of high interest to possible physics programmes at a future lepton collider. Since it’s discovery at Fermilab in 1995, there have been no lepton colliders operating with sufficient energy to produce top quarks – unlike the charm and bottom quarks, which were studied in further detail in lepton colliders after their discovery in hadron machines. The production threshold for top quarks is 350 GeV, and no lepton colliders capable of this energy have been constructed, meaning that the advantages of a lepton collider have never been utilised to understand the top quark in greater detail.

The detailed study of top quarks and their properties that would be made possible by a lepton collider would have many benefits, primarily in the precision of the measurements. Similar to the Higgs, low QCD backgrounds make top quark events easier to reconstruct. The fact that the collision is between elementary particles, rather than a parton-parton collision as in a hadron collider, also permits more well-defined centre of mass energy, which is not possible in hadron colliders.

Precision measurement of the top quark is an important test of the SM – many BSM models envision their additional particles as partners of the top quark. The upshot of this is that because of this, these theories propose properties of the top quark that diverge from the SM. In-depth and precise analysis of the top quark’s properties would place limits on these theories.

[...] [$t\bar{t}$ production threshold studies – these form an idealised QCD system to study, possibly also a $t\bar{t}$ bound state]

Energy	Reaction	Physics goal
91 GeV	$e^+e^- \rightarrow Z$	ultra-precision electroweak
160 GeV	$e^+e^- \rightarrow WW$	ultra-precision W mass
250 GeV	$e^+e^- \rightarrow Zh$	precision Higgs coupling
350-500 GeV	$e^+e^- \rightarrow t\bar{t}$	top quark mass and couplings
	$e^+e^- \rightarrow WW$	precision W coupling
	$e^+e^- \rightarrow \nu\bar{\nu}h$	precision Higgs coupling
500 GeV	$e^+e^- \rightarrow f\bar{f}$	precision search for Z'
	$e^+e^- \rightarrow t\bar{t}h$	Higgs coupling to top
	$e^+e^- \rightarrow Zh h$	Higgs self-coupling
	$e^+e^- \rightarrow \tilde{\chi}\tilde{\chi}$	search for supersymmetry
	$e^+e^- \rightarrow AH, H^+, H^-$	search for extended Higgs states
700-1000 GeV	$e^+e^- \rightarrow \nu\bar{\nu}hh$	Higgs self-coupling
	$e^+e^- \rightarrow \nu\bar{\nu}VV$	composite Higgs sector
	$e^+e^- \rightarrow \nu\bar{\nu}t\bar{t}$	composite Higgs and top
	$e^+e^- \rightarrow \tilde{t}\tilde{t}^*$	search for supersymmetry

Table 2.1: Physics processes of interest at lepton colliders up to 1 TeV.

2.2 The International Linear Collider

The International Linear Collider (ILC) is a proposed high-luminosity linear electron-positron collider based upon 1.3 GHz superconducting radio frequency (SCRF) accelerating technology. The ILC would have a centre of mass energy of 250 GeV in the initial stage, upgradable to 500 GeV and then to 1 TeV at a later date. The total footprint of the complex would be 31km in length, with the arms using magnets with an accelerating gradient of 31.5 MVm^{-1} in metre-long superconducting nine-cell niobium cavities operating at 2K.

One of the unique features of the ILC is the “push-pull” detector system. This is a moving platform in the chamber housing the interaction point (IP), upon which two detectors can be mounted. The platform can be moved to exchange which detector is in the interaction point, allowing a linear collider to function with multiple detectors. This allows the two detectors to specialise for different physics studies and goals, much like the various experiments at the LHC at CERN, which would normally not be possible with a linear collider.

There were a number of proposed sites for the ILC, including Fermilab in the United States, CERN in Geneva, DESY in Hamburg, and JINR near Moscow. The most recent possible site, which has had significant attention and planning devoted to it, is the Kitakami Highlands region of Iwate prefecture in Japan. This would be a greenfield site, located on the side of a mountain range and requiring that a significant amount of the facility's infrastructure be located underground, in tunnels dug within the granite rock of the region.

The ILC project published a Technical Design Report (TDR) in [20XX?] with extensive details of the technology and ongoing research and development into making the collider a reality. Current timeline estimates say that construction could start in [year], commissioning of the experiment would begin in [year], and first physics would be achieved in [year].

A report from the Science Council of Japan (a representative organisation of the Japanese science community) released in early 2019 expressed that they had not reached a consensus as to whether to support hosting the ILC in Japan. Some of the reasons cited were concerns over international cost-sharing in the long-term, as well as whether the expected scientific outcomes would justify the unprecedented human resource requirements and infrastructure necessary to make the ILC a reality [1].

On 7th March 2019, the Japanese government released a statement to say that they would not be making a proposal to host the collider. They however expressed a keen interest in the future of the project, and that they would be continuing to contribute towards the research and development of the ILC.

2.2.1 ILC detectors

Detector design for the ILC is driven by the requirements of the physics programme – many of the physics goals and targeted processes are highly dependent upon hadronic states, so precise jet reconstruction and high jet energy resolution is critical to meeting the expectations placed upon the ILC.

The only technique thought to be capable of delivering the necessary level of accuracy is *particle flow*. Particle flow is an integrated approach which uses algorithms to examine the flow of energy through all parts of the detector to correlate different signals together to generate particle flow objects (PFOs). The requirements for the use of particle flow is a very good separation of charged and neutral particles, translating into a need for high-efficiency trackers, and calorimeters capable of high-efficiency reconstruction of neutral

particles. The design of the detectors for the ILC has proceeded from these requirements.

The need for large separations between charged and neutral particles requires that the vertex detector, tracker, and calorimeter systems are contained within a magnetic field, so that charged particles' path is curved by the field. In general, this separation depends on the physical size of the detector and the strength of the magnetic field. Thus there are essentially two basic approaches to detector design: a large detector with a lower magnetic field, using the size of the detector to separate charged particles from neutral particles; or a more compact detector utilising a much stronger magnetic field to create the same separation.

These two approaches are shown in the two detector concepts for the ILC – the International Large Detector using a 3.5T magnetic field, and the more compact Silicon Detector using a much stronger 5T magnetic field. These two detectors will be discussed in detail below.

The International Large Detector (ILD)

The International Large Detector (ILD) is a detector concept for the ILC intended as a multi-purpose detector, with a strong focus on optimising the performance of particle flow algorithms as much as possible. To attain this, it uses several technologies for very high-resolution and high-efficiency tracking, as well as highly-granular calorimeters.

For vertex tracking, the ILD uses three double-layers of pixel detectors using monolithic active pixel sensor (MAPS) technology, with a spatial resolution of $4\ \mu\text{m}$ and a timing resolution of $2\text{--}4\ \mu\text{s}$. For tracking, the ILD uses a hybrid system, combining a gaseous time projection chamber (TPC) with silicon detector layers placed both inside and outside the TPC volume. This combination allows a high tracking efficiency with a low material usage.

The calorimeter system must be highly granular in order to best utilise particle flow. The calorimeters are split into the electromagnetic calorimeter (ECAL) and hadronic calorimeter (HCAL). The ECAL utilises a silicon diode sampling calorimeter with diode pads of $5 \times 5\ \text{mm}^2$. An option for an ECAL using thin scintillator strips is also being investigated. The HCAL has two possible options available. The Analogue Hadronic Calorimeter (AHCAL) uses silicon photomultipliers (SiPM) on tiles of plastic scintillator with a resolution of $3 \times 3\ \text{cm}^2$ using a fully analogue readout. The Semi-Digital Hadronic Calorimeter (SDHCAL) uses resistive plate chambers (RPC) with a higher granularity of $1 \times 1\ \text{cm}^2$, but does not use a fully analogue output, meaning that amplitude information

is more limited.

These detectors are placed within a solenoid capable of generating a 3.5T magnetic field, and then within an iron flux return yoke which is instrumented for muon identification and tail catching, as well as providing structural support for the detector. The finished ILD is expected to weigh 14,000 metric tonnes.

Figure 2.1: Rendering of the finished ILD cutaway to show the internal features (left); and a quadrant view of the ILD components (right).

The Silicon Detector (SiD)

The Silicon Detector (SiD) is a detector concept for the ILC that uses primarily silicon-based technology, with the aim to reduce cost while still maintaining high performance and attaining the ILC's physics goals. The SiD is also more compact than the ILD, utilising a stronger magnetic field to compensate.

The vertex and tracker systems are both composed of silicon sensors, using a cylindrical configuration. The vertex uses silicon pixel sensors while the tracker uses silicon strip sensors, both designed to be used with power pulsing – the electronics are only powered and active when it is known that bunches will be colliding. This reduces power and cooling requirements.

The high-granularity calorimeters are both nested within the barrel, inside the magnetic field. The ECAL uses thirty alternating layers of tungsten absorber and silicon active layers, in $3.5 \times 3.5 \text{ mm}^2$ hexagonal pixels. The HCAL uses alternating layers of steel absorber and a glass resistive plate chamber, with cells of $10 \times 10 \text{ mm}^2$.

Outside of the calorimeter, the superconducting solenoid generates a 5T magnetic field, which enables the more compact detector design – a higher magnetic field increases the

Figure 2.2: Visualisation of a simulated $e^+e^- \rightarrow t\bar{t}h$ event in the ILD. Charged particles can be easily identified by the curved or spiral paths they take within the magnetic field, and the jets are visible as the light pink and purple areas near the beampipes on either side.

spatial separation between charged and neutral particles, which is necessary for usage of particle flow algorithms.

Outside of the magnetic field is an iron flux return yoke, which similarly to the ILD concept also acts as a structural support and is instrumented for muon identification and tail catching.

2.3 The Compact Linear Collider

The Compact Linear Collider (CLIC) is a proposed linear electron-positron collider that would be located at CERN in Geneva, Switzerland. The accelerator is a staged design, with the initial stage having a centre of mass energy of 380 GeV, focusing on precision measurements of top quark and Higgs physics. The further stages would increase the centre-of-mass energy to 1.5 TeV, then finally 3 GeV. Physics goals in these later stages would involve searches for new physics processes, as well as precision measurements of rare Higgs processes, and of new states discovered at the LHC or earlier stages of CLIC.

To attain these extremely high energies, the CLIC accelerators will be able to produce accelerating gradients as high as 100 MVm^{-1} . These cannot be achieved with traditional

Figure 2.3: Isometric view of the finished SiD cutaway to show the internal features (left); and a quadrant view of the SiD components (right).

klystrons due to the extremely high peak RF power needed. Klystrons capable of providing this would be inefficient and prohibitively expensive, so the CLIC accelerators plan to use a two-beam acceleration scheme. A drive beam is used, with low intensity but high power. RF power is then extracted from the drive beam to power the main accelerator. In this way, the high power, shorter duration pulses can be achieved more economically, allowing the high acceleration gradients that will allow each arm of CLIC to accelerate electrons up to 1.5 TeV in only 21km.

The proposed site for the CLIC experiment would be at CERN, built beneath the existing LHC ring and stretching across the French-Swiss border, running parallel to the feet of the Jura mountain range. This placement is determined by the geological features of the region around Geneva and the feet of the Juras, where the tunnels would be dug into the sedimentary ‘molasse’ rock in the area.

As of writing, the CLIC project released a Conceptual Design Report (CDR) in 2010 detailing the current state of planning for the experiment. It has also submitted input to the European Particle Physics Strategy Update, which will decide which projects the CERN collaboration chooses to pursue from 2020 onwards.

The detectors envisioned for CLIC are similar in design to those for the ILC, and are usually referred to as CLIC_ILD and CLIC_SiD. See [2.2.1](#) for a detailed description of these detector concepts.

2.4 The Future Circular Collider

The Future Circular Collider (FCC) is a series of concepts for a future collider that would be located in the Geneva area near the existing LHC ring. The FCC project as a whole has three different accelerator concepts – the FCC-hh for proton-proton and ion-ion collisions, the FCC-ee for electron-positron collisions, and the FCC-he for electron-proton collisions.

The initial proposal is to construct a circular electron-positron collider – the FCC-ee – with a circumference of 100km and delivering a maximum centre-of-mass energy of 365 GeV. The motivation for this is that at this energy range – the electroweak scale – the FCC would be able to access the Z pole, the W- and top-pair production thresholds, as well as producing a large number of Higgs bosons.

Unlike linear colliders, staged energy increases are not part of the FCC-ee plan. The usage of low-mass particles like electrons in a circular collider results in a high energy loss due to synchrotron radiation, which must be mitigated by the constant addition of energy. Significantly higher energies than those planned by the FCC-ee are not currently practical due to these losses. Instead, the FCC-ee would concentrate on a physics programme in the 90-365 GeV energy range, leveraging the much higher luminosities available to a circular collider compared to linear colliders in the same energy range.

A further part of the proposal for the FCC is that following the conclusion of the physics programme of the FCC-ee, the tunnels and infrastructure would be re-used for the FCC-hh, a hadron collider. This follows in the footsteps of the LHC, which was constructed in tunnels originally built to house the Large Electron Positron Collider (LEP). It is claimed that the FCC-hh built in these tunnels would be able to reach centre-of-mass energies of at least 100 TeV.

According to the given timeline, the FCC-ee would begin construction in 2028, and first physics would take place in 2039.

2.5 The Circular Electron Positron Collider

The Circular Electron Positron Collider (CEPC) is a proposal for a circular electron-positron collider with a circumference of 100km that would be hosted in China, with a centre of mass energy of 240 GeV to operate as a Higgs factory. It is also intended to operate at 91 GeV and 160 GeV to produce large numbers of Z and W bosons. This lower centre of mass energy is due to considerations of energy loss via synchrotron radiation.

However, the CEPC collaboration intends to utilise these to produce several synchrotron radiation light sources, including two gamma-ray beamlines.

The CEPC project released a Conceptual Design Report (CDR) in 2018 detailing the current state of planning for the experiment. It has also been submitted as input to the European Particle Physics Strategy Update. The current timeline envisions a five-year research and development period from 2018-2022, and construction to start in 2022, completing in 2030. The physics programme is expected to last for ten years, concluding in 2040.

Similarly to the FCC, it is expected that technology for superconducting magnets at high field strengths will have developed sufficiently to allow the tunnels to be used to house a high-energy hadron collider, called the Super Proton Proton Collider (SPPC).

The detectors of the CEPC as outlined in the CDR are very similar in design to the ILD, in the design of using a silicon vertex tracker, a TPC tracker, and similar options for the calorimeters. An additional difference is the optioning of a dual-readout calorimeter to replace the electromagnetic and hadronic calorimeters.

There would be two interaction points around the ring, allowing both detectors to operate at the same time, as opposed to the ILC's push-pull system. More information on the proposed CEPC detectors can be found in [reference].

Chapter 3

Data acquisition software

Before software can be reusable
it first has to be usable.

Ralph Johnson

Data acquisition is a critical component of all modern particle physics experiments across all stages of technological readiness, from the very beginning of hardware testing in tabletop experiments to full-scale international experiments like the Large Hadron Collider.

In the modern era of particle physics, the interplay of hardware and software at minuscule timescales drives everything, and almost all results are highly dependent upon the speed and efficiency of the electronics and computer systems that extract data from the detectors. A massive quantity of work goes into creating, testing and optimising the systems that will acquire, process, sort and transport data before it is ever seen by the physicist operating the experiment.

Of particular interest in this thesis is the data acquisition software during the development phase, where individual detector subcomponents are undergoing prototyping and testing. These development and iteration cycles are tied closely to testbeam facilities such as the Super Proton Synchrotron (SPS) at CERN and the DESY II synchrotron at DESY. At this point in the development cycle, the detectors are beginning to take shape and this is where data acquisition (or DAQ) becomes an important consideration.

In addition to this, the data acquisition solutions used during the testbeam phase of detector development is likely to inform the final data acquisition solution; either by evolving directly into the final software, or by identifying and evaluating the particular features or challenges of the subdetector components that the software must take into account or accommodate.

During this stage, each individual detector component – such as a vertex tracker or

hadronic calorimeter – will be developed by small teams, and the natural tendency is for each of these groups to set their own standards and develop their own tools, prioritising the features that are important to their specific case. However, in the past this approach has generated a variety of *ad hoc* solutions for testbeam software, many of which cannot be applied outside of their original scope. This results in different teams solving the same problems and implementing the same solutions for each subdetector.

An alternative to this is to develop a suite of tools or frameworks that are generic – capable of being used and deployed for a wide variety of different uses and detector types. In this way, we could greatly reduce the effort used to recreate the same solutions for each new detector, allowing more science to be done faster.

Online monitoring and data quality monitoring

The area of this that we have chosen to contribute to is the development of online monitoring and data quality monitoring tools. Data from testbeams is often not processed fully until well after it has been taken, sometimes after the testbeam has ended, due to constraints on time or processing power. If there were errors, incongruencies, or any other issues with the data, these issues cannot be identified immediately, and as a result may be present in multiple runs, spoiling data and wasting precious time during the already extremely time-sensitive environment of a testbeam.

Online monitoring addresses these issues by allowing the experimenters to see a “preview” of the data being collected. It can provide both a quantitative and qualitative look into how the detectors are responding, and what the data will look like when properly processed, allowing any potential issues to be identified and fixed in a timely manner. This means that good online monitoring can improve the efficiency of a testbeam, increasing the “yield” of data from a given experiment.

Another aspect of this is data quality monitoring (DQM), which assesses the ‘quality’ of the data being taken. The definition of data’s ‘quality’ will vary depending on the hardware, software, and goals of the experiment, but will usually constitute a some from of statistical measure. In this regard, data quality monitoring can be seen as an extension of the concept of online monitoring, focusing more closely on the quantitative aspects. In general, DQM provides the most benefit in more mature experiments, relying on previous experience with the detector and collected data to understand how the data appears when the device is functioning correctly.

In pursuit of all of the above aims, this chapter will discuss the Data Quality Monitoring

for High-Energy Physics tool (DQM4hep) developed for online monitoring and data quality monitoring, going into detail on its properties, principles, applications and development. Deployment and usage of the framework will be discussed in greater detail in Chapters 4 and 5.

The AIDA-2020 project

This work on DQM4hep takes place within the context of the AIDA-2020 project, an EU-funded research programme for developing infrastructure and technologies for particle physics detector development and testing, comprising 24 member countries and lead by CERN.

The overarching goal of AIDA-2020 is to develop common tools and infrastructures for physics testbeams. The collaboration is split into work packages focusing on specific areas, and the work detailed in this thesis takes place within Work Package 5 for data acquisition systems for beam tests

The goal of this work package is to create a suite of tools that are designed with a variety of possible uses in mind, thereby reducing the work and development time necessary to implement data acquisition and monitoring setups, speeding up the planning and deployment of physics testbeams.

3.1 Overview of DQM4hep

Data Quality Monitoring for High-Energy Physics (abbreviated DQM4hep) is an online monitoring and data quality monitoring framework developed for physics testbeams for high-energy and particle physics, developed by Rémi Eté and Antoine Pingault. It is designed to be able to fulfil the requirements of monitoring for physics testbeams in a generic way. The framework is written in the C++11 standard and can run on any Linux distribution. The only requirements for installation are a compiler compliant with the C++11 standard, cmake 3.4 or higher, and ROOT 6. All other dependencies are downloaded and compiled automatically during installation.

The two core principles of DQM4hep are genericity and modularity. The framework is based upon a plugin system that allows shared libraries to be loaded and hook classes for further use [2]. This structure allows for independent components of the framework to be used, not used, or exchanged, by isolating each function of the program into independent processes. The components that are specific to any particular use case are written by the users, and the rest of the framework then handles packaging this information in a useful

way and networking to transmit it to where it is needed, meaning that the user does not have to worry about the mechanics of data storage, serialisation or transmission.

The experiment-specific components have to be written by the user, but these components use standard C++ code with a few DQM4hep-specific functions to handle their integration into the framework, making them easy to understand for users who already have experience coding in C++. This also means that the framework is capable of working with any data format that can be packed into, decoded from, and accessed with normal C++ methods, including those that can be loaded from external libraries. This results in a framework that is able to deal with any kind of data, including user-defined data types, making it more flexible, portable and easily reusable.

3.1.1 Architecture

DQM4hep is designed with genericness as its core paradigm, using processes and algorithms that are independent of data type. The ability to run multiple instances of each process of the framework is also key to its flexibility, allowing users to, for example, separate sub-detector data from data that has undergone event building, operate in online or offline modes, or distribute the computational load of the analysis over several networked computers.

The generic nature of the framework lies in two core features:

- The Event Data Model abstraction allows the user to define the type and structure of an event and how serialisation should be handled.
- The plugin system allows the inclusion of any user-defined classes via external libraries, such as to select the serialisation process, online analysis, etc.

The plugin system for end-users consists of four different types of plugins: analysis modules, standalone modules, file reader plugins, and file streamer plugins. Each of these will be discussed in-depth in the sections below.

A diagrammatical representation of the overall structure of the framework can be seen in Fig. [3.1](#).

Analysis modules

Analysis modules receive events from the data acquisition system, processing the data according to a user-specified procedure to create ROOT TObjects like histograms, graphs,

Figure 3.1: The global online architecture of DQM4hep. Each block is colour-coded to show which operator of the testbeam is responsible for the process.

Figure 3.2: The structure of running DQM4hep online using an analysis module.

plots, etc. The analysis module then handles encapsulating these objects as monitor elements, and sending them to the rest of the framework for display and storage.

An analysis module is specific to one use case, and is intended to be written by the user with their data format and processing needs in mind. However, the framework provides both templates and examples for how to write an analysis module.

An example of the structure of the framework utilising an analysis module can be seen in Fig. 3.2.

Standalone modules

Standalone modules are identical in form to analysis modules described above. The distinction is that a standalone module does not operate on data coming from the data acquisition device. One of the intended and most common usages of standalone modules is as a slow control, taking data from monitoring sensors on the device rather than data, to report on the condition of the hardware. Standalone modules could also be used to *generate* data, if needed, acting as a programmed signal generator or random number generator.

An example of the structure of the framework utilising a standalone module can be seen in Fig. 3.3.

File reader plugins

A file reader is a type of plugin that reads a file from the disk and packs it into a data structure necessary for usage within DQM4hep. They are used primarily for offline monitoring or data processing. File readers can be made for any kind of file, provided the user understands the data structure. There are existing examples of file readers for data stored as binary, plain text, LCIO files, and ROOT TTrees.

An example of the structure of the framework utilising a file reader plugin can be seen in Fig. 3.4.

File streamer plugins

A file streamer is a type of plugin that reads data from a stream and packs it into a data structure necessary for usage within DQM4hep. They are for receiving data from a data acquisition device for online monitoring. File streamers can be made for any kind of data stream, provided the user understands the data structure. File streamers are considered the “default” in DQM4hep.

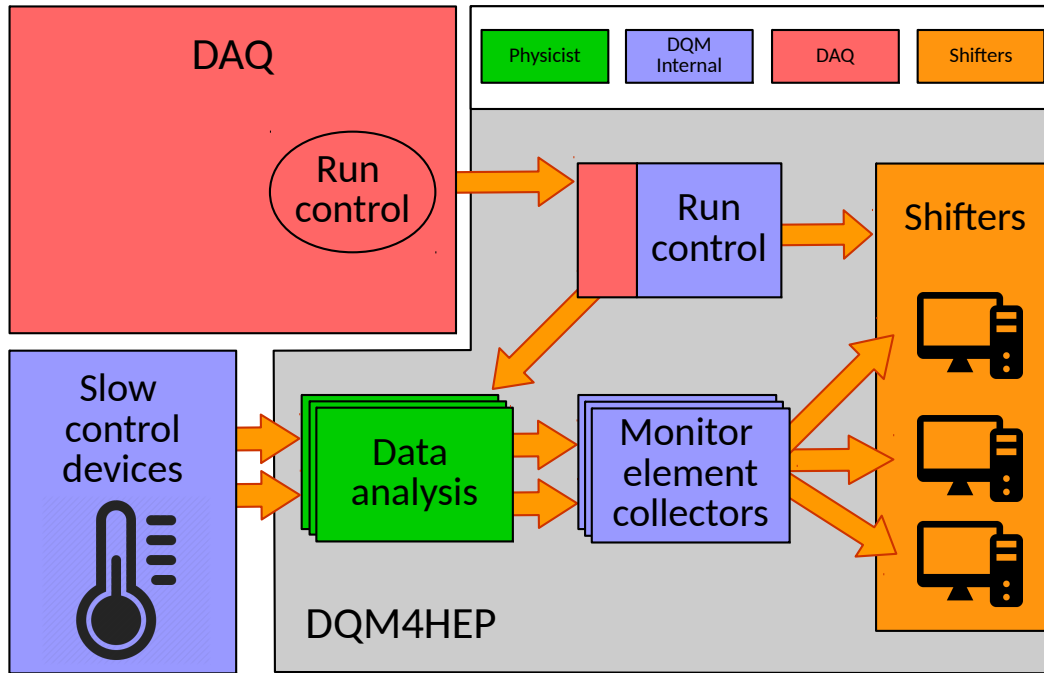

Figure 3.3: The structure of running DQM4hep online using a stand alone module.

Figure 3.4: The structure of running DQM4hep offline using a file reader module.

3.1.2 Visualisation and graphical user interface

As of writing, the graphic user interface (GUI) and visualisation elements of the framework are still under active development for a new version. Therefore this topic will be split into two sections: one to describe the existing GUI, and one to discuss the motivations and goals for the new GUI under development.

Current GUI and visualisation

The current version of the GUI is built with Qt, a free and open-source toolkit and framework for creating OS-independent graphic user interfaces and widgets. The motivation for choosing Qt was that ROOT provides an option for integration between ROOT and Qt, allowing ROOT classes like `TCanvas` to be “embedded” into Qt widgets. This simplified the implementation of a GUI, allowing a graphical interface based on Qt to be written, then graphics from ROOT simply opened within the existing widgets and windows.

This interface is used in multiple places, including the run control process and the monitoring GUI. The monitoring GUI is built on a system of canvases. Each canvas can have multiple plots open, which can be resized, maximised, minimised, etc. and manipulated as normal for ROOT plots. The user can also create new canvases for more space to arrange plots.

In addition to this, there is an optional provision for a monitoring steering file, which contains presets of canvases, and the plots displayed on them. This is extremely useful when dealing with large datasets or large numbers of plots, as the plots required by the user can be opened automatically when the monitoring interface is run.

An example of the Qt-based monitoring GUI in use can be seen in Fig. 3.5.

New user interface and visualisation package

For the newer versions of DQM4hep, the decision was made to overhaul the GUI and visualisation packages, removing Qt from the framework and moving to a web-based interface.

The removal of Qt was motivated by two reasons. Firstly, the integration with ROOT provided some complications, since running DQM4hep’s Qt-based GUI requires an installation of ROOT compiled with the `--enable-Qt` flag enabled. The majority of ROOT installations in remotely-accessible file systems based at CERN and DESY (which are heavily used for analysis and testbeams) were not compiled this way. Secondly, Qt was

Figure 3.5: An example of the current Qt-based monitoring GUI in use.

an additional dependency that must be installed prior to use, making the software more dependent upon the operating system, compiler tools, and environment of the machine, and thus less generic and easy to use.

The removal of the Qt UI allows for greater freedom with UI development. The intended goal is to have a browser-based GUI, removing dependency on any external GUI libraries and allowing it to function on any device. This will also make it more user-friendly and convenient, as the interfaces for run control, networking, and data monitoring and quality display can be simply run in different tabs of a web browser.

As of writing, the web interface is under active development by Rémi Eté and is not yet complete. However, a mock-up of the web interface can be seen in Fig. 3.6.

3.2 Data quality monitoring

Data quality monitoring is a type of data monitoring where the data is tested using some form of statistical or mathematical process to produce a value corresponding to the “quality” of the dataset. This can take many forms, such as comparing an experimental dataset to reference data acquired from previous experiments, or requiring that the χ^2 or p-value of a dataset may need to pass a certain threshold to be considered valid.

Figure 3.6: A preview of the planned web-based monitoring interface.

The definition of the “quality” statistic will differ according to a variety of factors such as the type of data, the aim of an experiment, etc. Common examples are p-values, or binary tests where data that passes had a quality of 1, and 0 otherwise.

One of the benefits of data quality monitoring is that it provides a more reproducible and robust set of checks on data-taking, allowing quantitative analysis of the performance of a detector prototype. It can also be used as a way for shifters without detailed knowledge of the hardware, software, or physics to determine whether the detector is performing as intended during a testbeam when experts are not available, by using the quality statistics as a guide.

Previous versions of DQM4hep did not have infrastructure to support data quality monitoring, but this was added during refactoring in preparation for the next release version. Once this was in place, this permitted an array of quality tests to be developed, implemented, and tested.

A quality test (or ‘qtest’) processes a series of monitor elements (ROOT TObjects) according to a set of criteria defined in the test’s code. This test produces a numerical result between 0 and 1, referred to as the “quality”. Within the framework, quality tests are self-contained C++ code files, which hook into the framework’s system for execution. Quality tests are run by using the executable `dqm4hep-run-qtests` and a steering file to define parameters, such as which files to load, which quality tests to execute, and what the passing and failing boundaries are for each quality test.

The quality tests that have been implemented in DQM4hep are described in detail below. Each test requires a certain type of object as an input and has its own definition of what the “quality” statistic represents. Some quality tests also require a reference to compare against the input data, which is also described.

3.2.1 Property within expected test

This is a quality test that takes either a TH1 or TGraph object, and finds some user-defined parameter. The parameter must be one of: mean, mean90, root mean square (RMS), root mean square 90 (RMS90), or median. It then checks whether either: that this parameter is within a user-specified range; or that it is above or below the user-specified threshold. If a range is being used, the result is the p-value of the property being within the specified range. If a threshold is being used, then the result is 1 if the property passes the threshold, 0 otherwise.

3.2.2 Exact reference comparison test

This is a quality test that takes any TObject, and compares it to a user-specified reference object (which must be of the same type). The result is 1 if the two objects are exactly identical, 0 otherwise.

3.2.3 Fit parameter in range test

This is a quality test that takes either a TH1, TGraph, or TGraph2D object and plots a user-defined function onto it, solving for one of the parameters of the function, then checks it against a user-defined range. The result is the p-value of the parameter being within the specified range.

3.2.4 Kolmogorov-Smirnov test

This is a quality test that takes either a TH1 or a TGraph object, and performs the Kolmogorov-Smirnov test between that object and a specified reference. The result is the p-value of the Kolmogorov-Smirnov test. The Kolmogorov-Smirnov test is intended for unbinned data, not histograms, but ROOT provides a function for performing the Kolmogorov-Smirnov test on histograms, so this functionality is also included for the sake of completeness.

3.2.5 Pearson χ^2 test

This is a quality test that takes a TH1 object and performs the Pearson χ^2 test between that object and a specified reference. This test is analogous to the Kolmogorov-Smirnov test, but is designed specifically to work for binned histogram data. The result is the p-value output by the χ^2 test.

3.3 Adaptation to other detectors

Due to the modularity and genericity of DQM4hep, the process of deploying it for a new detector is simple – the only parts of DQM4hep that need to be made for any specific use case are the analysis modules, standalone modules, streamer plugin, and file reader plugin. For all of these plugins, there are templates available in the codebase, as well as examples of in-use plugins for other detectors. A few special DQM4hep-specific functions are necessary for these plugins to hook into the framework properly, but apart from these all user-provided plugins are written in normal C++ code that also integrates ROOT, so should be familiar to most users.

A file streamer or file reader must be written by the user given a specific data structure. This requires knowledge of both the event data model of the data acquisition setup, as well as the structure of the data files. The ideal person to write this code is someone with detailed knowledge of the data acquisition software being used, and the data storage or streaming.

In general, only one of the file streamer or file reader plugins will be needed. Both of these plugins are similar in structure and differ only on where they get the data from – a file reader loads a file from disk, whereas a streamer loads it from the data acquisition system. If the data will be monitored offline or “nearly-online” by loading files from disk, then a file reader plugin must be written. If the data is to be monitored online, then a streamer plugin must be written.

Once the information is accessible from either the file reader or streamer, the framework handles passing this data to the analysis modules. Analysis modules are a type of plugin which take data that has been packaged into events by a file reader or streamer plugin and performs some analysis on it. The main action an analysis module must do is create a monitor element (a ROOT TObject) then emit it to the rest of the framework. Before this step an arbitrary amount of processing can be done, e.g. checking validation bits, thresholds, error-checking, and so on. Monitoring the data quality can be done from

within analysis modules but this is not recommended as dedicated quality tests (see section above) are available.

For each analysis module that is being run, an XML steering file is required to provide the parameters and networking information to all the processes needed. A single steering file can call only a single analysis or standalone module, but multiple steering files can be run in parallel by the framework.

Examples of using DQM4hep with testbeams both within the AIDA-2020 community and outside of it can be found in Chapters 4 and 5, respectively.

3.4 Documentation and user manual

One of the biggest hurdles for the promotion and uptake of a new framework is the lack of understanding or familiarity with its use. Many research teams will continue to use existing software solutions, which may be suboptimal or difficult to use, according to the principle of “better the devil you know than the devil you don’t”. The first step to overcoming this is to produce clear, readable and complete documentation across the entire range of features the framework has.

The DQM4hep framework has two sets of documentation with different intended readers and different aims, so these will be discussed separately.

3.4.1 Doxygen documentation

Doxygen is a tool for automatically generating documentation resources for C++ code, relying on marked sections of documentation written within the actual code itself. Doxygen is able to directly obtain the structure of code, objects, functions, etc. from the code, allowing it to automatically generate a complex and rich set of documentation that categorises and indexes objects based on their inheritance, namespace, etc.

Doxygen can also generate an HTML- or L^AT_EX-based document that can be used as a local reference guide or hosted online. This makes Doxygen a powerful tool for documenting the technical aspects of code, demonstrating hierarchies of functions and objects, and an extremely useful reference guide for large programs or frameworks.

While Doxygen documentation is extremely useful, it does have some limitations. Doxygen functions more as a technical reference for code, lacking any overviews or instructions due to its automatic generation. This kind of documentation lacks a holistic element, and has no way for new users or those less familiar with the codebase to understand the overarching concepts. This can make it inaccessible for new users. The way this

was addressed will be discussed in the next section.

DQM4hep has a Doxygen website hosted on the internet, which is available here [4].

3.4.2 User manual

The existing documentation featured the common elements of the framework – such as the plugin system, event interface, logger, and XML parser – explained in detail, with clear examples and straightforward advice on their use.

My contribution to this was to write in-depth explanations on the structure, usage, and creation of analysis modules and quality tests, the two parts that are most specific to end-users. The experience I acquired using the framework and deploying it on testbeams for the first time, as well as integrating it with different detectors, provided a strong knowledge base to write the user manual intended for a user approaching the framework for the first time. These testbeams are described in more detail in Chapters 4 and 5.

The user manual can be found online here [3].

Analysis module guide

There is an in-depth explanation of each of the component functions of an analysis module, discussing which actions or data processing should be done in each, and their intended purposes. There is also an explanation of the XML steering files that are necessary to run an analysis module, and instructions on how the executable is run, along with its arguments.

In addition to this there is a worked example of an analysis module from start to finish. A simplified particle physics detector and its data format is defined, and then the reader is lead through the process of writing an analysis module step-by-step and function-by-function to obtain certain plots and results from the data. This is intended to give a more concrete demonstration of usage, as an easier to follow example. This section is also written in simple and plain English in order to be as accessible as possible.

Along with this documentation there is the `dqm4hep-example` Github repository [cite], which contains all of the code used in the analysis module user manuals, as well as the required `cmake` and `make` files to begin compiling projects right away. The intention of this repository is for new users to make a copy, write their own modules, and have everything needed for compiling and running them “out of the box” straight away. The user manual references this repository, so that users can see the files from the worked example in their full form.

Quality testing guide

There is extensive documentation of quality testing; each quality test is described in detail, including their purpose, output, required parameters, and optional parameters. In addition to this, there is a guide for how to run quality tests, including an explanation of running from the command line and an in-depth look at the structure of the XML steering files required.

Finally there is a section explaining how to write new quality tests. This includes a detailed explanation of the purpose of each function within a quality test file, what the required outputs are and how to utilise them, error testing, and advice on maintaining a style consistent with the rest of the framework.

Chapter 4

AIDA-2020 testbeams

I love fools' experiments.
I am always making them.

Charles Darwin

One of the most important aspects of testing and developing DQM4hep was to ensure that it was as generic as it was intended to be, and this meant deploying and using the framework on physics testbeams. DQM4hep was originally developed during testbeams of the Silicon Tungsten Electronic Calorimeter (SiWECAL), and its early testing phases were predominantly based on this detector, so it was apparent that it could be used in the originally-intended setting. However, in trying to develop it as a generic monitor, and to satisfy the requirements of a generic data monitoring and quality monitoring tool for AIDA-2020, it was essential that it was tested on other detectors of different types to demonstrate its generic nature.

In this chapter, deployment, testing and usage of DQM4hep on testbeams within the AIDA-2020 collaboration will be discussed in detail. For a testbeam where DQM4hep was deployed outside of the AIDA-2020 community, see Chapter 5. Three testbeams will be described in detail, as they represent the different stages of using DQM4hep as a data monitoring tool, from first implementation and deployment, to further developments, and finally as a mature tool integrated into the workflow of a testbeam.

CALICE testbeams

The CALICE testbeams were done with the *Forschung mit Lepton Collidern* (FLC)¹ group based at DESY in Hamburg, working on the Analogue Hadronic Calorimeter (AH-CAL) prototype during its development. Regular testbeams were held at the DESY II

¹EN: Research with Lepton Colliders

synchrotron at DESY in Hamburg, Germany and at the Super Proton Synchrotron (SPS) at CERN in Geneva, Switzerland. The goals for these testbeams varied over time but common focuses for the hardware were power-pulsing tests, and commissioning and calibration of new detector boards to test variations and changes to the manufacturing process. The testbeams were often used as testbeds for data acquisition electronics and software, such as the EUDAQ data acquisition software, the BIF device, and DQM4hep.

DQM4hep was used as an online monitoring and data quality monitoring tool for AHCAL testbeams beginning in May 2016, and in further testbeams between 2016 and 2018. The majority of these testbeams occurred at the DESY II facility, but two took place at the CERN SPS in May 2017 and June 2018.

The AHCAL prototype

The Analogue Hadronic Calorimeter (AHCAL) is a sampling calorimeter formed of steel absorber plates and plastic scintillator tiles, read out by silicon photomultipliers (SiPMs) as active material [5]. One of the important features of the AHCAL is that the prototypes were designed to be made using techniques suitable for mass production, such as injection-moulding and automated foil-wrapping of the scintillator tiles, and pick-and-place assembly of the layers and their electronics. It also uses power pulsing – rapidly cycling power so that the electronics are active only when the beam is present, according to a known beam structure. This helps to reduce power consumption and heat production, making cooling the layers easier.

4.1 May 2016 at DESY II

The first deployment of DQM4hep on an AHCAL testbeam was at DESY II during May 2016. The testbeam was to be two weeks in duration, following a one-week setup and preparation period. Besides testing the deployment and usage of DQM4hep, the goals of this testbeam were to test MIP calibration of a new AHCAL base unit (HBU), to test the power pulsing feature, and to perform TDC calibrations. In addition to these goals for the AHCAL, a device called a Beam Interface (BIF), another part of the ongoing work of AIDA-2020 Work Package 5, was being tested.

Before and during the testbeam, the majority of the development for AHCAL-specific analysis modules was undertaken. Prior to this, DQM4hep had only been used on SiWECAL beams, and was untested for other detectors.

File reader and streamer plugins for the LCIO data format were already available in

the now-deprecated `dqm4ilc` package, which meant that the framework could open and access the data format already.

4.1.1 Data format

The data for the AHCAL is in the Linear Collider Input/Output (LCIO) format, using an object type called `LCGenericObject`, which is a generic format for use when the existing data formats are not suitable. It comprises two parts: the block of data itself, held in 14-bit numbers; and a header containing user-defined parameters, in this case a timestamp, a typename for the object, and a description of the data contained in the object.

The structure of a single event in `LCGenericObject` format can be seen below, which is the result of using the `dumpevent` tool to dump the contents of an LCIO event to the command line:

```
----- print out of LCGenericObject collection -----

flag:  0x0
parameter DAQquality [int]: 1,
parameter DataDescription [string]: i:CycleNr:i:BunchXID;i:EvtNr;i:
    ChipID;i:NChannels;i:TDC14bit[NC];i:ADC14bit[NC],
parameter Timestamp [string]: Tue, 09 Feb 2016 18:20:43 +0100,
parameter TypeName [string]: CaliceObject,

[  id  ] i:Type,i:EventCnt,i:TS_Low,i:TS_High - isFixedSize: false
-----
[00000004]  i:0; i:15; i:15; i:0; i:36; i:12423; i:12422; i:12421;
            i:12420; i:12419; i:12418; i:12417; i:12416; i:12415; i:12414;
            i:12413; i:12412; i:12411; i:12410; i:12409; i:12408; i:12407;
            i:12406; i:12405; i:12404; i:12403; i:12402; i:12401; i:12400;
            i:12399; i:12398; i:12397; i:12396; i:12395; i:12394; i:12393;
            i:12392; i:12391; i:12390; i:12389; i:12388; i:12459; i:12458;
            i:12457; i:12456; i:12455; i:12454; i:12453; i:12452; i:12451;
            i:12450; i:12449; i:12448; i:12447; i:12446; i:12445; i:12444;
            i:12443; i:12442; i:12441; i:12440; i:12439; i:12438; i:12437;
            i:12436; i:12435; i:12434; i:12433; i:12432; i:12431; i:12430;
            i:12429; i:12428; i:12427; i:12426; i:12425; i:12424;
```

In this case, the `TDC14bit[NC]` and `ADC14bit[NC]` are arrays, each holding a number of elements equal to the `NChannels` variable, in this case 36. Each element of these arrays corresponds to a single physical scintillator tile within the detector, and identifies which chip it belongs to using `ChipID`.

The `ADC14bit` and `TDC14bit` arrays contain binary data, which is represented above converted directly to decimal. However some bits represent data other than the actual ADC or TDC, such as validation bits, hit bits, etc. An explanation of the structure of these bits can be seen in [ref].

[...]

4.1.2 Results

Over the course of the preparation week, the foundations were laid for the analysis module. This involved gaining a familiarity with the data structure, loading data from previous testbeams into DQM4hep offline, and attempting to read it in basic ways. The first module was not ready for the beginning of the testbeam proper, but a few days afterwards we were able to produce plots in DQM4hep from “nearly-online” testbeam data.

The first analysis module developed was the `AHCALRawModule`. The majority of the processing in this module was decoding of the data from the binary format and extracting the information from it. After this, validation bits and hit bits in the data were checked to classify data as ‘good’ or ‘bad’ hits. Then the actual ADCs and TDCs were filled into their respective histograms.

The first module acted as a proof-of-concept, and once this was done further work started on creating more modules with a wider variety of features and plots to provide better coverage for online monitoring. We created and refined two separate modules during this testbeam – `AHCALRawModuleChannel` and `AHCALRawModuleGlobal`.

The channel module created a per-spectrum channel of all ADCs, integrated over the whole run. It was able to load a number of individual channels, though due to the memory requirement, it could not track all channels simultaneously. To work around this, we implemented a facility for the module to read which channels to monitor from the XML steering file, so that these could be defined at runtime. An example of some of the per-channel spectra created using this module can be seen in Fig. 4.1

The global module produced a 2D histogram containing cells for each channel, coloured

Figure 4.1: Histogram produced by `AHCALRawModuleChannel` showing an ADC spectrum of a single channel for one run. The pedestal can be seen at approximately 300 and the MIP peak at around 650.

Figure 4.2: Histogram produced by `AHCALRawModuleGlobal` showing all ADCs exceeding 300 over a single run. Dead or nonresponsive channels are seen as white squares. The horizontal gaps are due to the fact that some ChipIDs were not present.

Figure 4.3: A full screencapture from the May 2016 testbeam showing the monitoring interface in use during power pulsing tests, displaying a MIP scan.

for the ADC in that channel. This didn't produce a hitmap as the geometry information was not available in this plot, but did allow easy identification of dead channels and channels that were in the beamspot. An example of this can be seen in Fig. 4.2.

Overall, once the monitoring had been set up and initial bugs and problems fixed, it became a routine tool of the testbeam. This was made easier by the usage of XML steering files for the monitoring interface canvases, allowing groups of plots and histograms to be automatically opened when the monitoring interface was started. This meant that with little effort, all information necessary for monitoring was easily available.

An example of the monitoring interface in use can be seen in Fig. 4.3.

4.2 July 2016 DESY II

The next usage of DQM4hep was a testbeam during July 2016, also at the DESY II facility. The testbeam was to be one week long, with a one-week preparation period. The primary goal for DQM4hep in this testbeam was to establish hitmaps of the calori-

meter. This would give a visual representation of the layers, allowing identification of the beamspot, allowing dead or mis-calibrated channels to be identified visually.

Creating a hitmap for the AHCAL was nontrivial, as the information coming from the data acquisition device and stored in LCIO format did not encode location. Each channel was instead identified by its “electronics number” – a combination of the ChipID of the board the channel was located on, and the number of the channel on that board.

Each layer was formed of four boards (each one with a ChipID), each of which contained sixteen layers. The orientation of the boards, which boards were in a layer, and the order of the layers in the stack were all changeable, so an additional requirement for the hitmap function was that it could take an external geometry file that could be changed or automatically generated.

DQM4hep has internal functions for parsing XML data, so an XML file was chosen as the format to store the geometry data. By making this an XML file, it avoided hard-coding the geometry into the framework itself, allowing the geometry data to be changed at runtime. XML also has the benefit of being human-readable. The AHCAL team already used an internal format for the geometry file for offline processing after testbeams, which was constructed and converted into different formats via a shell script, so this could be replicated for the DQM4hep XML file.

For analysis modules needing geometry, the XML file was given as a required parameter for the steering file, which then built a C++ map of the correspondence between electronics number and (i, j, k) co-ordinates of each channel in memory during initialisation. Then a function called `electronicsToIJK` was written that took the electronics number as the argument and returned the position of the channel in geometric co-ordinates. A further function was written, called `IJKToElectronics`, that performed the opposite operation, but this was not used.

Using these new functions, another analysis module called `AHCALHitmap` was written that created a two dimensional histogram, with each bin representing a channel on the x and y axes for a single layer. This histogram was then filled with the ADCs of that channel for the whole event, producing a hitmap.

The analysis modules for creating hitmaps were prepared ahead of the testbeam, and used extensively. They were used to identify channels that were dead or nonresponsive, as well as to confirm already-known nonresponsive channels.

Figure 4.4: A hitmap for a single layer during the July 2016 testbeam, showing all channels with ADCs higher than 300. The beamspot is clearly visible in the centre.

Figure 4.5: A collection of hitmaps for four layers in the stack during the July 2016 testbeam. The beamspot is visible, as are several dead or unresponsive channels in the top-left and top-right hitmaps.

4.3 May 2017 at CERN SPS

During May 2017, testbeam time at CERN’s Super Proton Synchrotron (SPS) facility was used for further tests for the AHCAL. One of the goals for this testbeam was to evaluate the performance of the power pulsing feature in magnetic fields up to 1.5T. The process of manufacturing the detector layers and boards was being automated, and a larger number of layers were available for this testbeam, so it also presented a way to test using a larger number of channels than before.

Part of the programme for the testbeam was to use the electron and muon beams available at the SPS for calibrating the newly-produced layers, as well as doing an energy scan with a pion beam.

The monitoring with DQM4hep in this testbeam included analysis modules that monitored the individual channels of all 40 large layers, as well as producing hitmaps of several types, such as unweighted, ADC-weighted, and near-pedestal. Standalone modules monitoring the temperature of the detector hardware was also used.

At this point in the testbeam process, the online monitoring system with DQM4hep had matured, partially due to the data format of the detector having been fixed for some time. Experience with running, using, and modifying the analysis modules had been disseminated throughout the team, and team members wrote their own analysis modules for producing plots.

Because of this, during the testbeam DQM4hep was used as intended – as a tool for shifters to use to diagnose and troubleshoot problems with the beams or detectors. A specific expert on DQM4hep was not necessary, as enough people operating the testbeam understood DQM4hep to be able to modify analysis modules on the fly according to their needs.

Chapter 5

IDEA testbeams

[new quote split
over two lines]

[author]

While DQM4hep was intended from the beginning as a generic tool, it was developed largely within the AIDA-2020 collaboration, which also promoted a variety of standards and guidelines for data acquisition devices, data formats, etc. In addition to this, it was also only tested on calorimeter-type detectors within the CALICE collaboration. To be sure that DQM4hep was truly generic – capable of adapting to *any* detector – it was necessary to test it on a wider variety of detectors outside of the AIDA-2020 and CALICE collaborations.

An ideal opportunity arose for this in the form of the IDEA testbeam. This testbeam was run by a collaboration of Italian and US universities working on four different particle physics detectors of different types, intending to run a single combined testbeam of all four instruments at the CERN SPS in September 2018. DQM4hep was offered as a possible unified monitoring solution that could integrate information from all four detectors into the same tool. This provided convenience for the teams operating the testbeam and detectors, and an extremely valuable opportunity to test DQM4hep out of its established operating range.

5.1 Introduction

The combined testbeam took place between in September 2018 at the CERN SPS beamline facility. The testbeam itself lasted a week, from the 5th-12th September, with a preparation period of one week before this for installation, calibration, etc. [...]

Detectors at the combined testbeam

The combined testbeam comprised four separate detectors: a calorimeter, a muon detector and preshower, a drift chamber, and a silicon photomultiplier. One of the biggest challenges involved in the testbeam was operating these four different detectors [...]

RD52 calorimeter

The Dual Readout Method (DREAM) calorimeter, also called the RD52 calorimeter, is a dual-readout calorimeter built, developed and tested by the RD52 collaboration by researchers based in universities at Gagliari, Cosenza, Pavia, Pisa, Rome, Iowa State and Texas Tech.

The aim of the calorimeter is to use both the Čerenkov and scintillator techniques simultaneously (hence “dual-readout”) to improve calorimetry, especially using calorimeters to measure four-vectors of jets and single hadrons, which suffer a reduced precision compared to electrons and photons. By comparing signals from Čerenkov light and scintillator light, the electromagnetic shower fraction can be measured on an event-by-event basis, eliminating the effects of fluctuations.

5.2 Monitoring

[...]

Existing monitoring within the DREAM collaboration could produce accurate histograms from raw data using ROOT, creating plots of the energy spectra of each detector

channel per event, along with [...]. This facility was reproduced in DQM4hep quickly using for-loops in both the C++ code and XML steering files, allowing this to be done with comparatively little code.

5.2.1 File readers

Writing file readers for the different detectors meant first understanding the structure of their data and file types. Once data has arrived from the data acquisition device, each of the detectors wrote to a different ‘raw’ format. However, the RD52 calorimeter, drift chamber, and muon and preshower all produced ROOT ntuple files as part of their data acquisition process, in addition to different file formats. It was decided to use these ROOT ntuples as the file format to read into DQM4hep, as due to support for ROOT within the framework, reading data from ROOT ntuples is simpler.

For each of these three instruments a file reader was developed that walked through the ROOT trees, extracting data from the leaves event-by-event, then converted it to DQM4hep’s inbuilt `GenericEvent` format. Choosing to make them into `GenericEvents` meant that there was no need to implement an additional event type, simplifying the connection between the file readers and analysis modules. The `GenericEvent` type was also easily suited to the type of data, as the majority of the data were series of numbers, which were easily converted into C++ vectors to store in the `GenericEvent`.

An additional motivation for using the ROOT ntuple as the data source was that some of the file type, notably the drift chamber, had not finalised their data structure at the beginning of the testbeam. Using the higher-level structure provided by a ROOT file would be easier to change in the future than reading in data in a binary, hex, text or CSV format.

For the silicon photomultiplier GEM data, the “raw” data format was a text file, containing an XML header followed by a large amount of data in Comma-Separated Values (CSV). This file could be loaded directly into DQM4hep, the XML header separated and parsed with DQM4hep’s internal XML parsing libraries, and the remaining data parsed. The comma-separated values could be easily parsed using the `dqm4hep::core::tokenize` function, which takes a string, a delimiter, and a vector, and parses the string into values separated by the delimiter, loading them into the vector. This made extracting the GEM data extremely simple, even in this format. It also allowed the parameters in the XML header, which included run numbers and physical information of the detector, to be passed into DQM4hep and the analysis module, using the `core::Run` object type.

5.2.2 Analysis modules

During the course of the testbeam, four analysis modules were developed, one for each detector. To begin with, these were ‘dummy’ modules – analysis modules that receive events then do nothing. Dummy modules like this are required to run file readers offline, but are simple to create as they can be produced from a template with minimal changes.

Once the file reader for the RD52 calorimeter was complete, the dummy analysis module for this detector was then changed into a functional module, `RD52MainModule`, to produce plots from the data. The RD52 was chosen as it was the most data-rich of the detectors in the testbeam, and also contained the ancillary detectors, which allow particle selection efficiencies to be studied.

During the course of the testbeam, the `RD52MainModule` was developed to read in and arrange data from the ROOT ntuples and arrange them into distinct vectors for the ADCs, TDCs, pedestals, and ancillaries. Following this, pedestal subtraction of all ADC and TDC channels was completed. Then the malfunctioning tiles and electronics that meant data had to be re-routed through other available channels was integrated so that the ADC information in the analysis module represented the full state of the detector was completed.

There was insufficient time at the testbeam to develop the monitoring more complex than this, but further development continued offline with saved data from the testbeam to continue the proof-of-concept. This will be discussed in more detail in the following section.

5.3 Results

Monitoring within DQM4hep was able to replicate all the existing monitoring solutions, combining the monitoring tools for all four detector systems into one framework. [...] However due to time constraints, more complex monitoring such as online processing was not implemented during the testbeam. [...]

Following the testbeam, it was decided that DQM4hep could be used to perform some offline analysis functions in addition to the work at the testbeam, as a further proof of its ability to do this at testbeams. [...]

Several analysis goals were outlined to attempt to implement in DQM4hep. These were performing the tower ADC calibration, the ADC to energy calibration, and particle selection efficiencies.

5.3.1 Tower ADC calibration

[...]

Due to a large number of tasks for setting up the testbeam, performing a calibration of the individual towers' high voltages was not possible, so the calorimeter ADCs were not calibrated to each other [?]. In order to fix this, [...]

Two sets of calibration runs were performed. The first set covered Towers 1-29 using an 80 GeV secondary beam (π and e^-), with the beam pointed at each tower in sequence for 29 runs. The second set used a 20 GeV electron beam, covering Towers 30-36 plus Tower 15. Tower 15 recieved runs in both sets in order to calibrate the two sets to each other.

[...] The run numbers corresponding to each tower is given in Table 5.1.

Tower	Run No.	Tower	Run No.
1	12545	16	12526
2	12556	17	12567
3	12558	18	12633
4	12560	19	12591
5	12601	20	12612
6	12638	21	12530
7	12598	22	12528
8	12514	23	12569
9	12518	24	12639
10	12521	25	12610
11	12600	26	12609
12	12636	27	12607
13	12539	28	12604
14	12628	29	12602
15	12512		

Table 5.1: Table of the run numbers and corresponding tower numbers for the calibration runs.

The process for calibrating the towers was to make a histogram of the ADCs registered in a tower, only in the run where the beam was centered on them, in order to find the mean and standard deviation. These histograms were then combined to show the overall

responses of the entire set of calibration runs, which visualises the differences between the Towers. These can be seen in Fig. 5.1.

Since Tower 15 was present in both runs, this was chosen as the reference, and all the other towers were given a coefficient that leveled their mean ADC to the same value as Tower 15, in both sets of calibration runs. The ADC values for each tower are then multiplied by their calibration coefficient. [...] [Difference between scintillator and Cherenkov] [...] The calibration coefficients are shown on Table 5.2.

Tower	Coefficient	Tower	Coefficient

Table 5.2: Table of tower numbers and their calibration coefficients.

5.3.2 ADC to energy calibration

[...] It was known from prior testbeams that the response of the calorimeter was linear with ADC, therefore the energy calibration could be extrapolated from a single datapoint. [...]

5.3.3 Particle selection efficiencies

An important result for the calorimeter was determining the efficiency with which it could determine the beam composition and select for certain types of particles based on

Figure 5.1: The plot of ADCs for each tower before calibration.

kinematic properties. The calorimeter was designed with a set of ancillary detectors to help discriminate between particle of different types. These provide a first selection of different particles, allowing us to use kinematic properties from the calorimeter itself to perform a second particle selection, and then compare the two.

The two ancillary detectors used for particle selection are the muon trigger and ...]
[...]

Using the calorimeter

[...]

One of the first steps is using the RD52 calorimeter data to find the energy ratio R for each event:

$$R = \frac{E_1}{\sum_{i=1}^n E_i}$$

where E_i is the energy of the i^{th} most energetic channel in the event and n is a nonzero integer. The choice of n [...]. Once the ratio R is calculated, a plot can be made of E_{total} vs. R for an entire run that shows separation of electrons from muons and pions – see Fig. 5.3.

An appropriate cut can be used to select electron events. [Information about the cut]. Adding in the information from the RD52's muon trigger, muons and pions can then also be separated. Using both the cut and the muon trigger, we can thus produce spectra for each individual type of particle in the run.

Figure 5.2: Comparison of the calibration plots for the ADCs before and after calibration.

[...]

The main goal of the data analysis is to characterise the response of the detector, and to measure the selection efficiencies of the detectors to various particle types. Once this is done, this will also give us a detailed account of the beam composition during each of the runs, which can be used for further work.

In order to do this, several ways to select for different particle types are necessary. The first way was using the preshower detector and muon trigger, which are both designed to discriminate between electrons and muons (respectively), with a high selection efficiency. These are used to create “reference” samples, [...]

The second way is to perform a kinematic selection using variables from the calorimeter. This is done using the E vs. R plot (normalised for beam energy) to select a region corresponding to a certain particle type. For example, the plot below shows this plot for Run [xxx] (X GeV hadrons) with the regions corresponding to hadrons and electrons highlighted. These regions overlap, meaning that attempting to select for hadrons using an ellipse around that region will also result in a non-insignificant number of electrons also being selected.

In order to perform a pure selection using the calorimeter, an extremely tight cut was used, focusing on the red spot at the centre of the hadron region. This ensures that the majority of events that pass the cut are hadrons, giving a high-purity selection. The purity of this selection can be assessed by using the appropriate preshower or muon trigger, excluding all non-hadron particles, and comparing the two numbers. If N_K is the number

Figure 5.3: Plot of E against R for the secondary hadron beam with $n = 10$ (Run 12709).

of particles passing the selection with only the kinematic cut, and N_{K+T} is the number of particles passing *both* the kinematic cut and the triggers, then the selection efficiency for hadrons ϵ_{hadron} is given by:

$$\epsilon_{hadron} = \frac{N_{K+T}}{N_K}$$

This was then done with the same process for electrons and muons, to obtain the individual selection efficiencies.

Chapter 6

Physics studies for the Compact Linear Collider

Somewhere, something incredible is
waiting to be known.

Carl Sagan

One of the primary goals of future lepton colliders like the ILC and CLIC is to become “Higgs factories” – machines that can produce large numbers of Higgs bosons in a variety of final states, allowing the Higgs sector of the Standard Model to be probed with unprecedented accuracy and coverage.

One of the uniquely accessible measurements for these colliders is a precision measurement of the top-Higgs Yukawa coupling. This serves as a further test for the Standard Model (SM) and [...]

Another important avenue to pursue is CP-violation in the Higgs sector. Since Higgs physics is still an emerging field, it is not yet known whether CP-violation is present in the Higgs sector to the degree that the Standard Model predicts. It is also a fertile area for investigation of BSM physics, as many BSM models predict additional Higgs bosons, or Higgs bosons with characteristics that differ from the SM Higgs.

The $e^+e^- \rightarrow t\bar{t}h$ event (see Fig. 6.1) is one process that is both accessible to CLIC’s design energy and extremely useful for interrogating the Higgs sector for CP-violation and BSM physics. The production of Higgs bosons allows for several observables that would be sensitive to any Higgs bosons with an odd CP quantum number (or “CP-odd” Higgs bosons). Determining the detectors’ sensitivity to the ratio of CP-odd and CP-even Higgs bosons (also called the CP mixing angle) will allow further understanding of the limits of the Standard Model, as well as the limits on the various BSM physics models, and regions

of interest for possible new physics.

[...]

Figure 6.1: A Feynman diagram of the $t\bar{t}H$ event.

There are three final states of the $t\bar{t}H$ event, which depend on the decays of the W^\pm boson. The W^\pm can decay into either a quark-antiquark pair, or a lepton-neutrino pair, so there are three possible final states: the *fully hadronic* case, where both W^\pm particles decay into quark pairs; the *leptonic* case, where both decay into lepton-neutrino pairs; and the *semi-leptonic* case, where one decays into a quark pair and the other into a lepton-neutrino pair. In general, the leptonic final state is not utilised for this analysis, so is not discussed further. Extended Feynman diagrams of the fully hadronic and semi-leptonic final states are shown in Figs. 6.2 and 6.3

[...]

[...] The invariant mass of the Higgs boson can be determined by summing the invariant masses of pairs of bottom quarks and computing the χ^2 for each possible combination; the combination with the lowest χ^2 shows the pair that has decayed from the Higgs boson.

[...]

6.1 Physics generation and samples

[...]

The Monte Carlo samples were generated predominantly using Whizard 1.95, though for the Higgs events, Physsim was used due to technical constraints of Whizard [ref?]. All samples were simulated at $\sqrt{s} = 1.4\text{TeV}$ and unpolarised beams, assuming an integrated luminosity of 1.5ab^{-1} and a light Standard Model Higgs boson with mass $125\text{GeV}/c^2$. See Table 6.1 for a summary of all of the used samples. The first two rows are the $t\bar{t}H$ signal channels, all other rows are background. The number of jets refers to the number of jets in the final state that have come from the decay of the top-quark pair. The number of

Figure 6.2: An extended Feynman diagram of the $t\bar{t}h$ event, showing the fully-hadronic decay channel with the final state $q\bar{q}q\bar{q}b\bar{b}$, where q and \bar{q} indicate a quark-antiquark pair.

Figure 6.3: An extended Feynman diagram of the $t\bar{t}h$ event, showing the semi-hadronic decay channel with the final state $\ell\nu q\bar{q}b\bar{b}$, where ℓ and ν indicate a lepton-neutrino pair of the same flavour but opposite [sign?].

[...]

[...] henceforth referred to as CLIC_SiD.

6.3 Sensitivity to cross-sections and Yukawa coupling

[...]

6.3.1 Analysis method

[...]

Sample processing

The first step is the initial jet clustering. This is done using the k_t algorithm with parameters [?], using an exclusive clustering mode to form 8 jets – 6 jets from the produced quarks and 2 beam jets. The k_t algorithm is used over choices like anti- k_t and

Valencia, because the important features are the *relative* shapes of the jets, rather than absolute properties, so there is no need to use more computationally-intensive [is this true?] algorithms.

Once initial jet clustering is finished, a Marlin processor that finds isolated leptons is used. It searches for either 0, 1, or 2 isolated leptons, and this information can be used to make decisions about whether to process the event already:

Leptons	Channel	Action
0	Fully hadronic	Use for fully hadronic analysis
1	Semi-leptonic	Use for semi-leptonic analysis
2	Fully leptonic	Discard

Following this, the two beam jets are removed from the processing, and a further step of jet re-clustering is performed, using the Durham algorithm, to [...]

[...] [Flavour tagging]

[...] [Tau finding]

The final step is to use PandoraPFAs to generate Particle Flow Objects (PFOs) of the undetectable particles, especially the top quarks, W^\pm , and Higgs. [...]

Analysis processing [?]

Once the sample has been processed, it must be analysed. The first step of this is a program used to extract various kinematic variables of both particles in the events (m_0 , p_t) and the event itself (Ψ , \mathcal{T}). This is the Treemaker program, and [...] [Chi-squared extraction of invariant masses] [Feeding into TMVA to generate BDTs]

[...]

[...]

6.3.2 Results

[...]

The combined uncertainty for the cross-section of both decay channels is:

Cross-section:

$$\Delta\sigma = 7.30\%$$

Then using this and a linear approximation from QCD [ref], the value of the uncertainty on the top-Higgs Yukawa coupling can be computed:

$$\frac{\Delta g_{tth}}{g_{tth}} = 0.503 \frac{\Delta \sigma(t\bar{t}H)}{\sigma(t\bar{t}H)} = 3.86\%$$

These results were contributed to a paper that summarised the top physics potential for CLIC at $\sqrt{s} = 1.4$ TeV, published in [journal][ref] and will be submitted to CERN's European Strategy Update in [month] 2019 [ref].

6.4 Determination of sensitivity to CP-violation

[...]

6.4.1 CP-sensitive observables

[...]

Up-down asymmetry

The up-down asymmetry is a conceptually simple observable that has already been identified for investigating CP-violation in the $t\bar{t}h$ process. It is found by defining a plane from the vectors of the incoming electron and produced antitop, then finding the ratio of top quarks that are emitted above and below this plane (see Fig. 6.4). If there is no CP-violation in this process, the ratio will be even.

Using the up-down asymmetry as an observable requires that the W^+ and W^- can be distinguished from each other, and has thus far only been used for the semi-leptonic decay channel. In this case, the lepton produced by the decay of one of the W bosons identifies its charge, and thus the charge of the top quark that it has decayed from. While this method was not previously possible in the fully hadronic case, a method for applying it by using jet charge determination is discussed in Section 6.4.2.

[other ones]

[...]

6.4.2 Jet charge determination

Previous analyses that have utilised the up-down asymmetry as an observable have focused exclusively on the semi-leptonic decay channel of $t\bar{t}h$ events, as the presence of a lepton emitted by the top or antitop quark offers a simple and statistically robust method to distinguish between the two top quarks. In the hadronic decay channel each top emits a

Figure 6.4: Geometric diagram of the up-down asymmetry in $t\bar{t}h$ events. The paths of the electron and antitop quark, and the angle ϕ between them define a plane. “Up-going” top quarks go above the plane, “down-going” top quarks go below.

jet, and even in the ideal case where each particle resulting from the jet can be accurately reconstructed, the net charge will *still* be an integer, since no particles with a non-integer charge can result from these decays.

However, techniques developed in recent years, intended primarily for observations in ATLAS at the LHC, have refined methods for this, and using the work of [reference], it is now possible to obtain the total net charge of the jet – that is, the charge of the initial quark that creates the jet.

This technique is strongly-dependent upon the accuracy and efficiency of both particle reconstruction and jet clustering, but these techniques are constantly improving, and Pandora Particle Flow Algorithms (PandoraPFAs) and new jet clustering methods are becoming increasingly sophisticated. Combined with the cleaner final states in a lepton collider, these techniques allow the charge of a jet to be determined with useful confidence.

The charge of a jet can be determined by summing the charges of all particles in the jet, weighted by p_T and normalised by the p_T of the entire jet:

$$Q_\kappa^j = \frac{1}{(p_T^{\text{jet}})^\kappa} \sum_{j \in \text{jet}} Q_j (p_T^j)^\kappa$$

Where κ is some parameter between 0 and 1, typically set to 1. With this technique, it is possible to determine between quarks with charges of $+1/3e$, $-1/3e$, $+2/3e$, and $-2/3e$ with [some level of confidence].

Jet clustering algorithms

Since this method relies upon jets it is strongly dependent upon jet reconstruction, and thus on the choice of jet clustering algorithm and parameters. Previous analyses of $t\bar{t}h$ events have used a two-step reclustering approach, using the k_t algorithm for the initial clustering and the Durham algorithm for reclustering. These algorithms were chosen as the relative difference between the jet shapes is more important than their absolute shapes, so other algorithms do not provide any benefits.

The Valencia algorithm, however, gives improved performance in the cleaner final states of a lepton collider, for which it was especially designed, and many analyses are now transitioning to using the Valencia algorithm.
